

# Character Set

## Definition

A **character set** is the collection of **all valid characters** that a C program can recognize and use. Every C program is built entirely out of these characters — digits, letters, special characters, and white space.

## The 4 Categories of Characters in C

| DIGITS                                                                                                               | LETTERS                                                                                                                                     | SPECIAL CHARACTERS                                                                                                                                                                                 | WHITE SPACE                                                                                                                                                                                         |
|----------------------------------------------------------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <ul style="list-style-type: none"><li>Numbers: <b>0 to 9</b></li></ul> Used in constants, numbers, array sizes, etc. | <ul style="list-style-type: none"><li>Uppercase: <b>A to Z</b></li><li>Lowercase: <b>a to z</b></li></ul> Used in variables, keywords, etc. | <ul style="list-style-type: none"><li>+ - * / % → Arithmetic</li><li>= == → Comparison/assignment</li><li>&amp;   ^ ~ → Logical/bitwise</li><li>; : ( ) [ ] → Structure &amp; separation</li></ul> | <ul style="list-style-type: none"><li>Space</li><li>Tab (\t)</li><li>Newline (\n)</li></ul> <b>Use:</b> separates tokens, improves readability, ignored by compiler (except inside string literals) |

## Note

- A character set forms the **raw alphabet** of C — every keyword, variable name, and symbol you ever write is built from these 4 categories.
- White space is normally **ignored** by the compiler, but inside a string literal ("like this") it is treated as meaningful text, not ignored.

💡 Fun Tip

Think of the character set as C's **full alphabet + punctuation box** — nothing outside it can be typed into valid C code!

# Tokens in C

## Definition

In a passage of English text, individual words and punctuation marks are called **tokens**. Similarly, in a C program, the **smallest individual units** that the compiler recognizes are known as **C Tokens**.

Just like a sentence is built from words, a C program is built entirely from tokens — the compiler breaks your code into these pieces before it can understand or execute it.

## Types of Tokens in C — 6 Types

## Quick Preview of Each Type

| Token Type         | What It Is                                            | Example         |
|--------------------|-------------------------------------------------------|-----------------|
| Keywords           | Reserved words with a fixed, predefined meaning       | int, if, return |
| Identifiers        | Names created by the programmer                       | marks, main     |
| Constants          | Fixed values that never change during execution       | 10, 3.14, 'A'   |
| Strings            | A sequence of characters inside double quotes         | "Hello"         |
| Operators          | Symbols that perform mathematical/logical actions     | +, >, &&        |
| Special Characters | Symbols that define structure and separate statements | { }, ;, ( )     |

Each of these is covered in full detail on the following pages.

## Note

- Every single character you type in a C program belongs to **exactly one** of these 6 token categories — nothing falls outside this classification.
- The compiler's very first job (called **lexical analysis**) is to split your raw code into this stream of tokens before checking grammar or meaning.

💡 Fun Tip

Tokens are to C what **words are to a sentence** — the smallest meaningful pieces!

# 🔑 Keywords, Constants, Strings & Special Symbols

| 🔑 KEYWORDS                                                                                                                                                                                                           | ⚙️ CONSTANTS                                                                                                                                                                           | { } STRINGS                                                                                                                            | ⚙️ SPECIAL SYMBOLS                                                                                                                                                                    |
|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <b>Reserved Words</b><br>Predefined words with a fixed meaning, reserved by C — <b>cannot</b> be used as variable names.<br><br><code>int, float, char, double, if, else, for, while, return, break, continue</code> | <b>Fixed Values</b><br>Do not change during program execution.<br><br>Numeric: <code>10, -25, 3.14</code><br>Character: <code>'A', 'z'</code><br>String Constant: <code>"Hello"</code> | A <b>sequence of characters</b> inside double quotes.<br><br><code>"Hello"</code><br><code>"C Language"</code><br><code>"12345"</code> | Characters that define <b>structure &amp; separate statements</b> .<br><br><code>{ }</code> → block of code<br><code>;</code> → end of statement<br><code>( )</code> → function calls |

## 💡 Why Each of These Matters

| Type                   | Why It's Needed                                                                                                                                     |
|------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------|
| <b>Keywords</b>        | Give the compiler its fixed vocabulary — without them, C wouldn't know what <code>if</code> or <code>return</code> means                            |
| <b>Constants</b>       | Represent values that must stay the same throughout the program (e.g. a fixed tax rate)                                                             |
| <b>Strings</b>         | Let a program store and display text (names, messages, sentences)                                                                                   |
| <b>Special Symbols</b> | Hold the program's structure together — without <code>{ }</code> and <code>;</code> , C wouldn't know where one instruction ends and another begins |

### 💡 Fun Tip

Keywords = C's **fixed vocabulary** 📖, Constants = C's **unchanging facts** 📌 — both are locked, unlike variables!

## ID Identifiers & Naming Rules

### 📖 Definition

An **identifier** is a **name created by the programmer** to identify variables, functions, arrays, structures, and other program elements.

```
int marks, total_sum;
void main();
char studentName[20];
```

`marks`, `total_sum`, `main`, and `studentName` are all **identifiers** — names the programmer chose.

## 💡 Rules of Identifier Naming in C

- ✓ **Allowed characters** → only letters (A-Z, a-z), digits (0-9), and underscore `_`  
`student1, total_marks, sum_2`
- ✗ **Must start with a letter or underscore** → cannot begin with a digit  
✓ `value1, _value` | ✗ `1value`
- ⚠️ **Case-sensitive** → `Name` and `name` are treated as two **completely different** identifiers
- ✗ **No special characters or spaces** → symbols such as `@` `$` `%` and spaces are not allowed  
✗ `total%marks`   ✗ `my name`
- ✓ **Cannot use keywords** (reserved words) → e.g. `int`, `float`, `return` can never be identifiers
- ✂️ **Length** → no strict limit in C, but most compilers only recognize the **first 31 characters** (ANSI standard)
- ✓ **Should be meaningful** (best practice) → improves readability  
`average_score, total_sum` — better than: `al`, `xx`

### 📌 Note

- An identifier's job is purely to give a **human-readable label** to something the compiler will track by address internally.
- Good identifier names are one of the easiest ways to make your code **self-explanatory** — always prefer `totalMarks` over `tm`.

### 💡 Fun Tip

Identifiers are like **name tags** 🏷️ you create yourself — just follow C's dress code for names!

# + Operators — Overview of All 8 Types

## Definition

**Operators** are symbols that tell the computer to perform some **mathematical or logical function** on one or more values (called operands).

## The 8 Types of Operators in C

| # | Operator Type                  | Symbols                                                                                                   |
|---|--------------------------------|-----------------------------------------------------------------------------------------------------------|
| 1 | Arithmetic Operator            | <code>+</code> <code>-</code> <code>*</code> <code>/</code> <code>%</code>                                |
| 2 | Relational Operator            | <code>==</code> <code>!=</code> <code>&lt;=</code> <code>&gt;=</code> <code>&lt;</code> <code>&gt;</code> |
| 3 | Assignment Operator            | <code>=</code> <code>+=</code> <code>-=</code> <code>*=</code> <code>/=</code>                            |
| 4 | Logical Operator               | <code>&amp;&amp;</code> (AND), <code>  </code> (OR), <code>!</code> (NOT)                                 |
| 5 | Increment / Decrement Operator | <code>++</code> <code>--</code>                                                                           |
| 6 | Conditional Operator           | <code>?</code> <code>:</code>                                                                             |
| 7 | Bitwise Operator               | <code>&amp;</code> <code> </code> <code>^</code>                                                          |
| 8 | Special Operator               | <code>&amp;</code> <code>*</code> (address-of / pointer)                                                  |

## One-Line Purpose of Each

| Type                  | Purpose                                                                             |
|-----------------------|-------------------------------------------------------------------------------------|
| Arithmetic            | Basic math: add, subtract, multiply, divide, remainder                              |
| Relational            | Compares two values → gives true(1)/false(0)                                        |
| Assignment            | Stores a value into a variable (plain or combined with math)                        |
| Logical               | Combines multiple true/false conditions                                             |
| Increment/Decrement   | Increases or decreases a variable by 1                                              |
| Conditional (Ternary) | Shortcut for a simple if-else, in one expression                                    |
| Bitwise               | Works directly on the individual bits of a value                                    |
| Special               | <code>&amp;</code> gets a variable's address; <code>*</code> dereferences a pointer |

## Note

- These 8 categories cover **every symbol-based operation** in C — from simple math to advanced pointer work.
- Several of these (Logical, Assignment, Increment/Decrement, Conditional) were already covered in detail with full examples in earlier notes — this page is your **quick-reference summary** of all 8 together.
- The **Special Operator** category (`&`, `*`) is the foundation of **Pointers**, covered in full in the Pointers notes.

## Fun Tip

8 operator types = 8 different **tools in your C toolbox** 🧰 — each built for a different job!

# 📦 Datatypes in C — Overview

## Definition

A **datatype** tells the **type of data** that a variable can store — like a number, a character, or something more complex.

## 3 Categories of Datatypes in C

| Category           | Includes                                                                                | Description                                                            |
|--------------------|-----------------------------------------------------------------------------------------|------------------------------------------------------------------------|
| 1. Basic / Primary | <code>int</code> , <code>char</code> , <code>float</code> , <code>double</code>         | C's built-in, fundamental types — every other type is built from these |
| 2. Derived         | <code>array</code> , <code>pointer</code> , <code>structure</code> , <code>union</code> | Built by combining or extending the primary types                      |
| 3. User-defined    | <code>typedef</code> , <code>enum</code> , <code>struct</code>                          | Custom types the programmer defines for their own use                  |

## 🔑 Primary (Basic) Datatypes — Full Breakdown

| Basic Datatypes (Primary) |                                                                                              |
|---------------------------|----------------------------------------------------------------------------------------------|
| Integer                   | Floating PointCharacter                                                                      |
| Branch                    | Sub-types                                                                                    |
| Integer → Signed          | <code>int</code> , <code>short int</code> , <code>long int</code>                            |
| Integer → Unsigned        | <code>unsigned int</code> , <code>unsigned short int</code> , <code>unsigned long int</code> |
| Floating Point            | <code>float</code> , <code>double</code> , <code>long double</code>                          |
| Character                 | <code>char</code> , <code>signed char</code> , <code>unsigned char</code>                    |

📖 The full details — explanation, significance, and a working example for **each individual sub-type** — are covered on the next page.

## Note

- Signed** types can store both positive and negative values; **unsigned** types store only zero and positive values, in exchange for a larger positive range.
- Choosing the right datatype affects both **memory usage** and the **range of values** your variable can safely hold.

## Fun Tip

Basic → Derived → User-defined = C's datatypes get **more custom-built** at each level! 🧱

# Integer Types — Full Detail

## All 6 Integer Sub-types

- int** (Integer)
- **Explanation:** Stores whole numbers (positive & negative).
  - **Significance:** Most commonly used for counting, indexing, etc.
  - **Example:** `int age = 20;`

- unsigned int**
- **Explanation:** Stores only non-negative whole numbers (0 and above).
  - **Significance:** Useful when negative values aren't needed — gives a larger positive range.
  - **Example:** `unsigned int population = 50000;`

- short int** (Short Integer)
- **Explanation:** Smaller range integer (uses less memory).
  - **Significance:** Saves memory when values are known to be small.
  - **Example:** `short int temp = -120;`

- unsigned short int**
- **Explanation:** Only positive short integers.
  - **Significance:** More positive range packed into small memory.
  - **Example:** `unsigned short int marks = 95;`

- long int** (Long Integer)
- **Explanation:** Larger range integer than normal int.
  - **Significance:** For big values like population, distance, etc.
  - **Example:** `long int distance = 123456789;`

- unsigned long int**
- **Explanation:** Only positive long integers.
  - **Significance:** Widest range for very large positive values.
  - **Example:** `unsigned long int stars = 400000000;`

### Fun Tip

**short → int → long** = small room, normal room, big warehouse 🏠🏡🏢 — pick the size you actually need!

## Character Types, Floating Types & void

### Character Types

- | signed char                                                                                                                                                                                                                      | unsigned char                                                                                                                                                                                                    |
|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <p><b>Explanation:</b> Stores characters or small integers (can be negative).</p> <p><b>Significance:</b> Represents characters with ASCII codes (-128 to 127).</p> <p><b>Example:</b> <code>signed char grade = 'A';</code></p> | <p><b>Explanation:</b> Stores characters or small integers (0 to 255).</p> <p><b>Significance:</b> Used for binary data, images, ASCII text.</p> <p><b>Example:</b> <code>unsigned char letter = 'B';</code></p> |

### Floating Point Types

- float**
- **Explanation:** Stores decimal numbers (single precision).
  - **Significance:** For storing fractional values like measurements.
  - **Example:** `float pi = 3.14;`

- double**
- **Explanation:** Decimal numbers with higher precision (double precision).
  - **Significance:** More accurate calculations than float.
  - **Example:** `double gravity = 9.80665;`

- long double**
- **Explanation:** Even higher precision decimal numbers.
  - **Significance:** Used in scientific and financial calculations.
  - **Example:** `long double atom_mass = 1.23456789012345;`

### The void Type

- void**
- **Explanation:** Represents "no value at all."
  - **Significance:** Used for functions that don't return anything.

Example

```
void greet() {
    printf("Hello, World!");
}
```

### Fun Tip

**void** = "nothing to return" ☹️ — like a function that just *does* something instead of *giving back* something!
